1. Introduction

The automobile industry has an increasing demand for lightweight components, improved product performance, efficiency and increased safety. To optimize the design and manufacturing of these components, detailed measurement of critical material properties such as strain limit, strength coefficients, anisotropy coefficients et al. are required. The most commonly used method for finding the material properties is tensile test with extensometer. But this system only provides an average strain over the specimen gauge length and is not applicable to post diffuse necking. The Digital Image Correlation (DIC) is a state of art technique that can be used for accurate strain measurement. Because of its capability for fast data acquisition, this technique is well suited for the characterization of material properties both in the elastic and plastic ranges. It also has advantages of full field, non-contact, and considerably high accuracy for displacement and strain measurements.

The modern manufacturing industry requires higher strength materials for more economical and light weight products. These new materials have to be tested to find the material properties required for production. Tensile test data such as stress-strain relation is critical for material processing, such as stretching, stamping, bending and so on. Most often, the traditional extensometer technique is used to measure the tensile strain between two points which provides average strain over an area. It is practically difficult to find the strain information at position of necking using the tensile test machine with extensometer. The measured strain is over the whole measured area between the extensometer probes. DIC system measures the full-range strain distribution during the tensile test.

This report will investigate the whole field lagrangian strain measurement with DIC in tensile test and compare the measurement result of DIC with the traditional method. Advanced High-Strength Steel (AHSS) materials including HLSA 350, DP600, DP780, DP780HY, TRIP780, and DP980 were tested. In this report, measurement of DP980 is used as an example to demonstrate the test process. The results for other materials are shown in the appendices.

3. Basic Theory of Digital Image Correlation

DIC tracks the position of the same physical points shown in a reference image and a deformed image. To achieve this, a square subset of pixels are identified on the speckle pattern around point of interest on a reference image and their corresponding location determined on the deformed image. A box shown in Figure 1 is an example of subset. The digital images are recorded and processed using an image correlation algorithm.

Many parameters are included while obtaining accurate DIC results. Some of the parameters include speckle size, speckle density, type of algorithm, subset size, subset overlap, gray level interpolation, etc. Highly optimized input parameters provide very accurate results. The focus of this section will not be on optimizing input parameters but rather investigating the accuracy and reliability of the DIC technique. Bornert's et al. work listed in the reference section gives a good assessment of the importance of input parameters.

The basic principle or the processing work is done by the software; it calculates the average gray scale intensity over the subset in the reference image and deformed image and compares them. Equation 1 shows the basic form of the cross-correlation term using the two consecutive images.

$$c(u, v) = \sum_i \sum_j L_1(r_i, s_j) L_2(r_i + u_L, s_j + v_L) \quad (1)$$

$$u_L = u + \frac{\partial u}{\partial r} \cdot (r_L - r_C) + \frac{\partial u}{\partial s} \cdot (s_L - s_C) \quad (2)$$

$$v_L = v + \frac{\partial v}{\partial r} \cdot (r_L - r_C) + \frac{\partial v}{\partial s} \cdot (s_L - s_C) \quad (3)$$

Here, u and v are the in-plane displacements of the center points of a subset located at (r_C, s_C) , and u_L and v_L are the displacements of an arbitrary point (r_L, s_L) in the subset. L_1 represents the intensity of subset pixels in the reference image. L_2 represents the intensity of pixel in the deformed image. Solving for the variables u and v gives the in-plane deformation in the x direction and y direction, respectively. The size of the subset is $2n \times 2n$. The complete term from Equation 1 gets different values at different positions in the deformed image. The maximum value of the term shows the matched position of the most similar pattern in the deformed image compared to the reference image. A more accurate approach is the normalized correlation equation. Equation 4 shows the normalized correlation equation.

$$C(u, v) = \frac{\sum_i \sum_j L_1(r_i, s_j) L_2(r_i + u_L, s_j + v_L)}{\sqrt{\sum_i \sum_j L_1^2(r_i, s_j) \sum_i \sum_j L_2^2(r_i + u_L, s_j + v_L)}} \quad (4)$$

In the Equation (4) the normalized correlation coefficient $C(u, v)$ reaches its maximum at one. The in-plane displacements can be determined by identifying a subset around a point at one position in the reference image and comparing it to the subset around a point in the deformed image having the same intensity distribution. Y.H. Wang's et al. study listed in the reference section gives a more thorough description of principal of DIC, T.C.Chu, J.S. Lyons and Hung P. C.

Calibrating the DIC system is a key process to ensure that the measured results are accurate. Both cameras can be calibrated at the same time. DIC calibration gives the metric information to relate the ideal model of camera to the actual physical device and to determine the position and orientation of the camera with respect to a world reference system. This metric information includes two kinds of parameters, intrinsic parameters and extrinsic parameters. The intrinsic parameters indicate the internal geometric and optical characteristics of the camera, such as focal length of the lenses, distortions of the lenses, and the positions between the lenses and CCD image device. The extrinsic parameters indicate the external geometric relation between the camera and the specimen, such as rotation matrix and translation vector. With the calibration data, DIC system can translate the image coordinate to geometric coordinate. The calibration plate should be placed in the same plane as that of the CCD chip of the camera and at a same distance as that of the specimen or in front of the specimen as shown below. Detail description about the calibration can be found by the literature [Y.H. Wang, T.C. Chu, and M.A. Sutton.].

The calibration can be initiated when the software shows the color pattern of dots as shown in the live image as shown below, this indicates that the plate is in the same plane or it is parallel to the CCD Chip plane. An image of the calibration plate is also shown below.

In our DIC setup, Redlake's Motion Pro X3 high speed camera was used. This camera combines excellent resolution to frame rate performance, along with the advanced features for accurate high speed motion analysis. The highest resolution of camera is 1280x1024 at 1000 frames per second. In our measurement, an interested area was chosen. The resolution of interested area is: 160x550 pixels, which corresponds to 12.5x43 mm, or with another word, one pixel corresponds to 0.078mm on sample surface. The length of the interested area is a little shorter than the gage length (50mm) of the extensometer due to shades. 12x12

pixels unit was chosen as subset for correlation calculation, the evaluated image is $(160-12) \times (550-12)$. That means we lost 6 pixels on each edge in the evaluated area.

4. Measurement Setup Using DIC and Extensometer

To measure sheet metal strain with the tensile test, 2D deformation setup is required (i.e. only one camera is needed). The picture above shows the experimental setup. A tensile test machine with an extensometer attached on the backside of the sample was used for measuring the conventional engineering strain-stress curve; the DIC system with a high speed camera was set in the front of the sample on a stable tripod to measure true strain over the whole area. The tensile test specimens used in the experiment were prepared according to the ASTM standards. To enable the DIC measurement, random speckle patterns were sprayed on the object surface; first with white spray paint and then with black spray paint. The pattern was as thin as possible.

During the measurement process, an image of the object was taken before and after the deformation and then the DIC system applied the correlation algorithm to quantitatively evaluate the data of contour, deformation and strain. The DIC system includes a high speed camera “REDLAKE, MotionPro X3 Plus” with lens “Nikon, AF Micro Nikon 60mm f2.8D”, which has full resolution of 1280×1024 when 2000fps. It was placed in front of the specimen as shown in Fig. 3.

The distance was adjusted between the camera and the specimen depending on the specimen area to be measured. The camera was connected to a computer with 2.13G CPU, 2G RAM and Windows XP Pro OS was used, in which the data is acquired and evaluated using the ISTR 4D software from Dantec Dynamic. In order to eliminate interruptions from surrounding light, a powerful green LED light source was employed to illuminate the sample and a corresponding filter (to let only the reflected green light go through) was utilized to let only the reflected green light go through the camera lens.

5. Traditional Method-Extensometer – Measurement result for DP980

Fig. 1 Measurement result of Eng. strain over time from extensometer

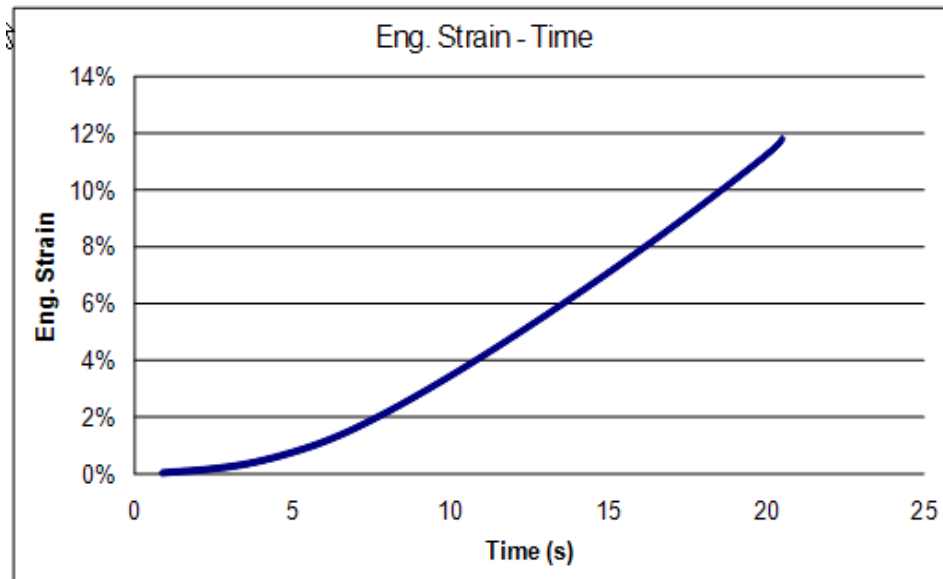

Fig. 2 Repeatability of eng. Strain over time

The loading speed or the strain rate for the specimen was set relatively low ($0.0084/s$ or $1in/min$), and the camera was set with the speed of 25 frames /second with a full resolution of 1280×1024 . Dual phase steels such as DP600, DP780 DP 980, TRIP780 and ECT with varying compositions were tested. Whole field true strain as well as the true strain in the necking area was displayed. In order to valid the measurement results, the gauge effect on the strain determination have been investigated and a comparison between different gauge lengths was carried out. Engineering Strain and Engineering Stress data in Fig. 1 and Fig. 2 were obtained directly from tensile machine.

Fig. 3 Eng. Stress-strain curve using extensometer

True strain and true stress in Fig. 3 and Fig. 4 were obtained by equation: $\epsilon_t = \ln(1 + \epsilon_e)$ and $\sigma_t = \sigma_e(1 + \epsilon_e)$

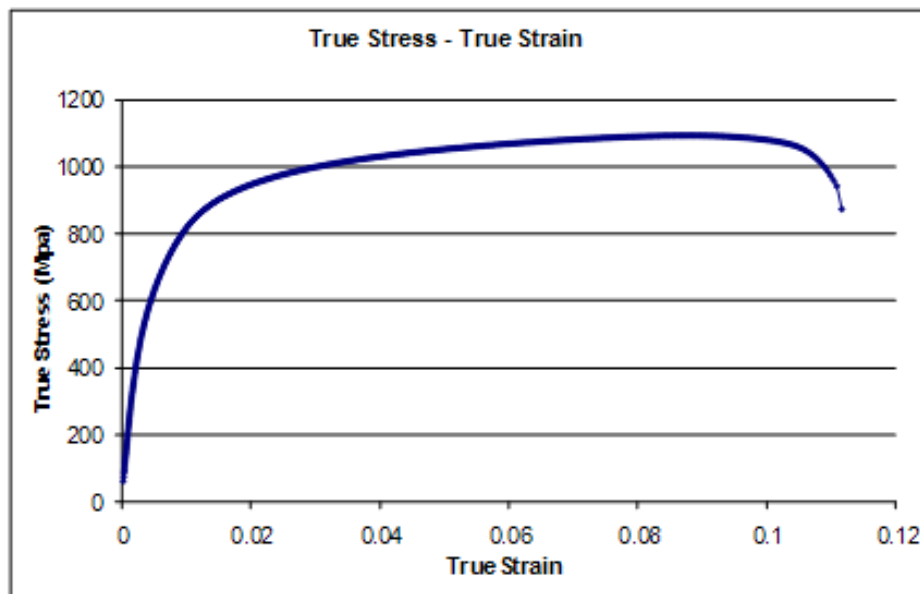

Fig. 4 True Stress-strain curve using extensometer

6. DIC Measurement System – Measurement result for DP980

Lagrangian strain is suited for determining strain with large deformation. Therefore, our DIC system measures Lagrangian strain. For suitable presentation of result the strains displayed in following charts have been converted to true or engineering strain as described below:

Denote L as two dimensional Lagrangian strain matrix:: $L = \begin{bmatrix} E_{11} & E_{12} \\ E_{12} & E_{22} \end{bmatrix}$
where E11, E22 and E12 are Lagrangian strains measured directly by DIC in x, y directions and shear strain respectively.

The two dimensional true strain matrix T is transferred by:
 $T = \frac{1}{2} \ln (2L+I)$

The two dimensional engineering strain matrix E is transferred by :
 $E = (2L+I)1/2 - I$,
Where I is the two dimensional unit matrix.

All true and engineering strains in the following slides are transferred according to the equations above except for some charts with special explanations.

Fig. 5 Database for whole field strain distribution as a function of time

Fig. 6 Strain-time profile of DP600 with DIC and extensometer

To compare DIC data with traditional method we have selected three points on the specimen. Point A & C represent the two ends of the extensometer. The strain values at these two points are very close to data from extensometer, but just a little smaller than extensometer's data after the necking. Point B represents the region of necking, which extremely larger than extensometer's data after the necking. Figure 5 and Figure 6 show the strain vs time at those points. Figure 7 shows the true strain along the line ABC over time. Figure 8 show the test repeatability of major strain measurements.

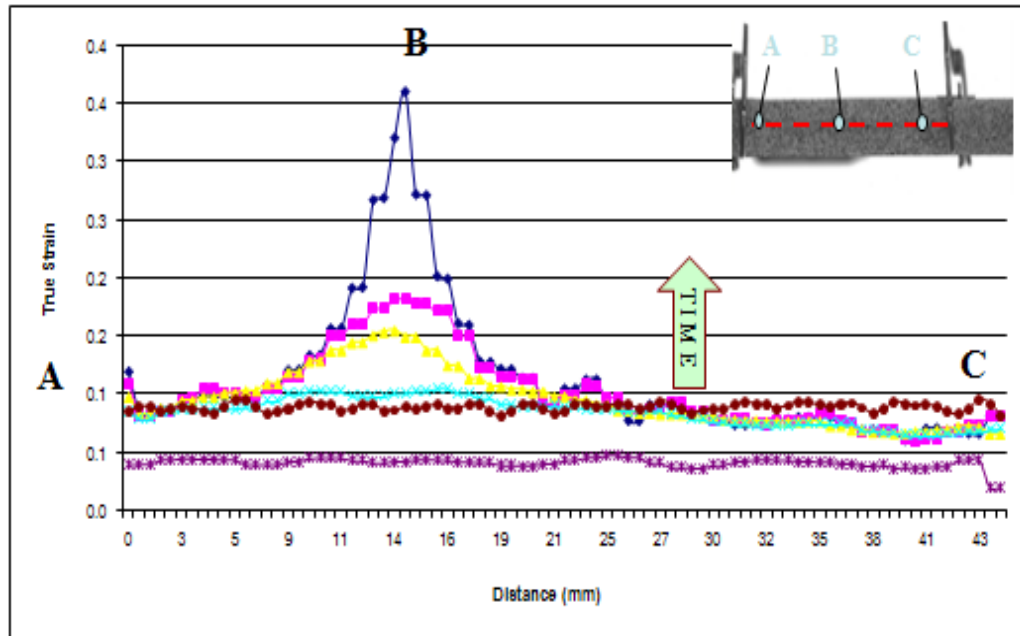

Fig. 7 Different colors indicate strain levels at different times during the test. Profile of axial strain along the red dotted line over time.

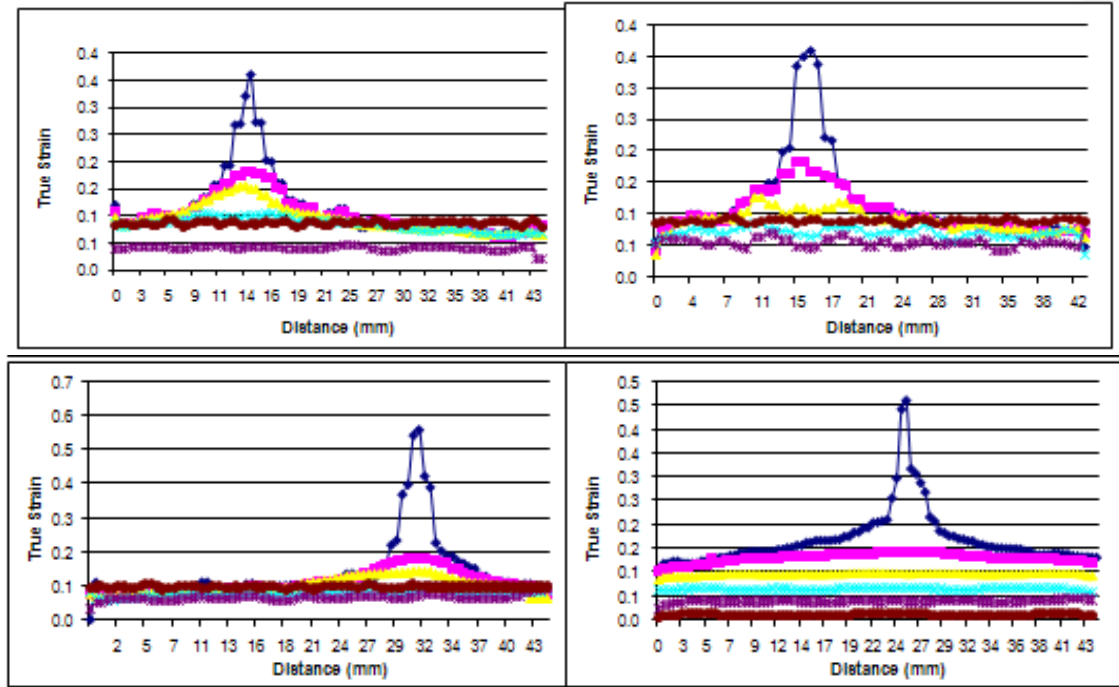

Fig. 8 Test Repeatability of Major Strain

Figure 9 shows the true Stress-Strain Curves at the Fracture Region (line 0). Obtained by converting Lagrangian strain measured by DIC to true strain as described before. The true Stress is calculated by $\sigma_t = \sigma_e(1 + \epsilon_e)$ Where: the *engineering stress* is obtained by MTS machine and the *engineering strain* is calculated $\epsilon_e = e^{\epsilon_t} - 1$.

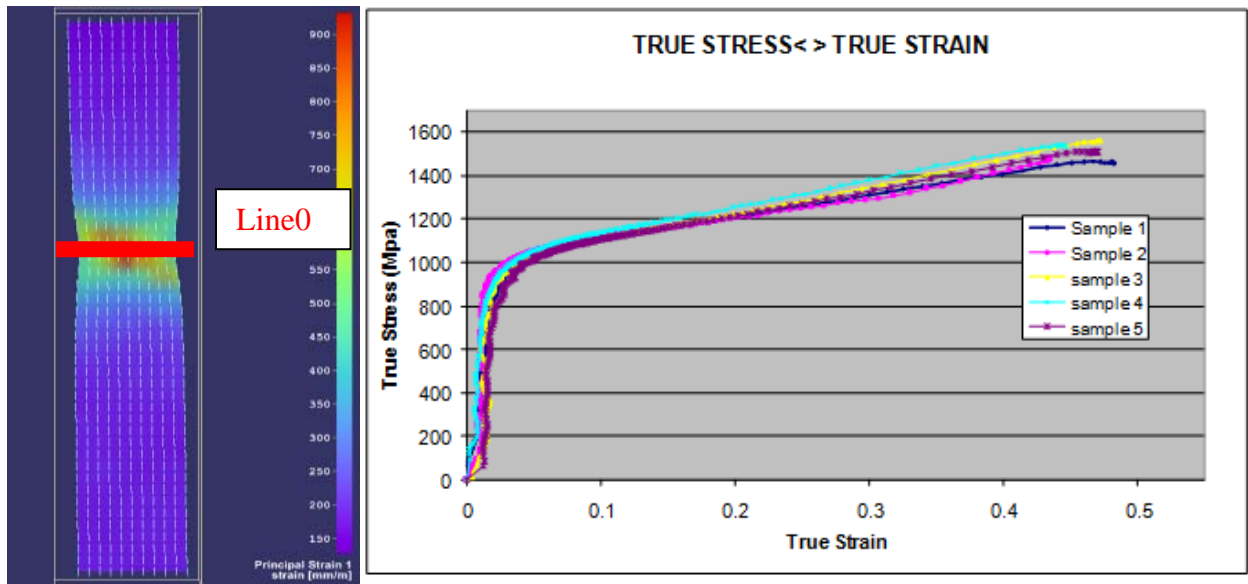

Fig. 9 True Strain-Stress Curves at the Fracture Region

Figure 10 shows the engineering Stress-Strain Curves at the Fracture Region (line 0). Eng. Strain: Calculated by $\varepsilon_e = e^{\varepsilon_i} - 1$, ε_i is converted from data measured by DIC. An averaged value over the line 0 is taken.

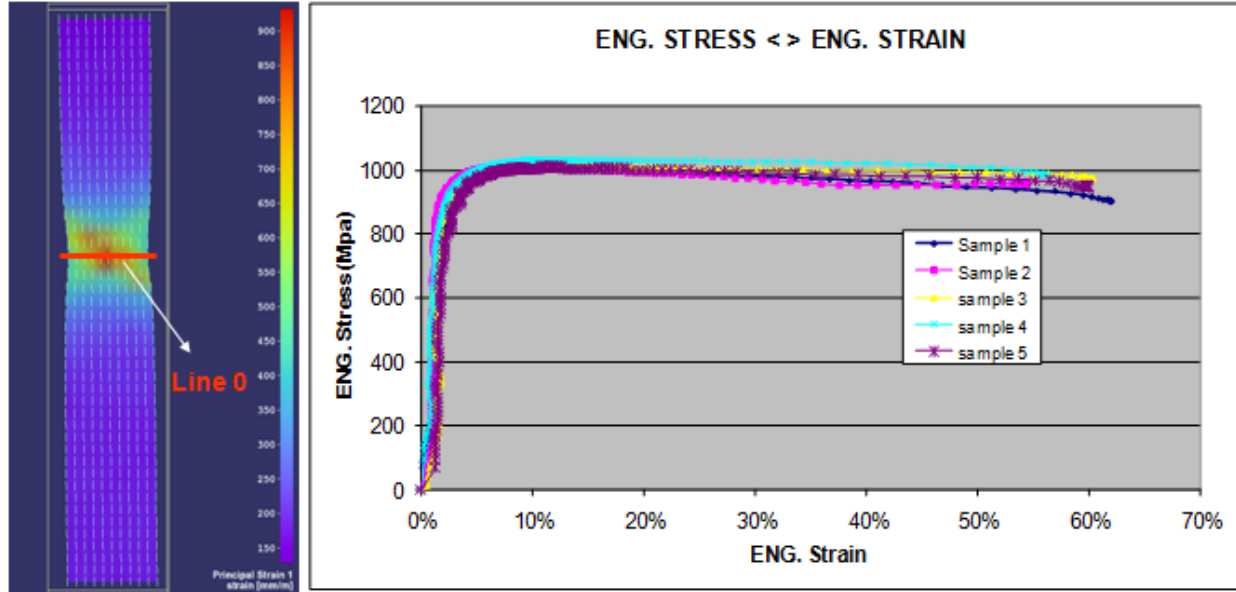

Fig. 10 Engineering Strain-stress Curves

7. Effect of Gauge Length

The tool used to prove the reliability of DIC is called "Gauge Effect of Stress-Strain Relationship", which is explained as follows:

The data was evaluated for various lengths within the extensometer gauge length. Different gauge lines relative to the line 0 (the fracture position) are shown in Fig. 11.

Here, we calculate the true strain based on: $\varepsilon_t = \ln(1 + \varepsilon_e)$, where the engineering strain is calculated by DIC data rather than from extensometer, it is calculated by the equation: (Change in length) / (Original length), where the original length is so called gauge length, the gauge length is the distance from a line to the line 0 (the fracture position). We used 5 different gauge lengths which are 1.5, 3, 6, 12.5, and 20 mm as indicated in the left image below. The line 1.5 means that the distance between lines 1.5 to line 0 is 1.5 mm. The change in length is the deformation between the two lines. It can be easily obtained by DIC data. Please note that we take an average of the deformation between two lines rather than only two points. We calculate the true stress based on: $\sigma_t = \sigma_e(1 + \varepsilon_e)$, where the engineering stress is taken from MTS machine, and the engineering strain is calculated by (Change in length) / (Original length), as described above.

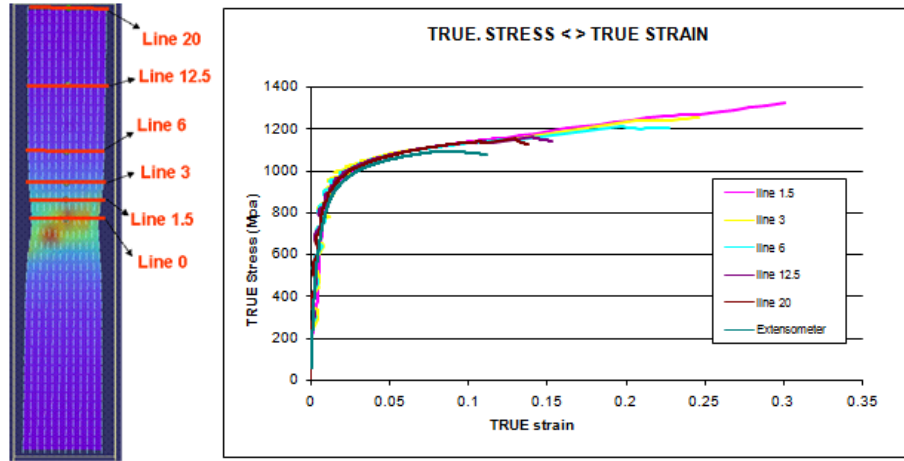

Fig. 11 Effect of gauge length on true strain-stress curve

From the true stress-strain and engineering stress-strain curves above it is observed that as the gauge length is increased from line 0 to line 20 (i.e. towards the extensometer probe) the stress-strain curve tends to move toward the extensometer curve. This indicates that the stress strain curves plotted using DIC data would overlap the stress strain curve plotted using the tensile test machine with extensometer data. The extensometer clamp covered the speckle pattern during recording, and therefore no data can be obtained at region around the clamp. This proves that the data acquired from DIC is highly accurate and reliable.

To further prove the reliability of the DIC system, a repeatability study was conducted. Fig. 9 and Fig 10 show the results for true stress-strain and engineering stress-strain curves for four samples of DP980. All curves are very close which demonstrate that the measurements have good repeatability.

The original length is called the gauge length, which is the distance from a line to the line 0 (the fracture position). We also took 5 different gauge lengths which are 1.5, 3, 6, 12.5, and 20 mm as indicated in the left image below. The change in length is the deformation between the two lines. It can be easily obtained by DIC data. Please note that an average of the deformation between two lines rather than only two points is taken. The engineering stress is obtained by MTS machine.

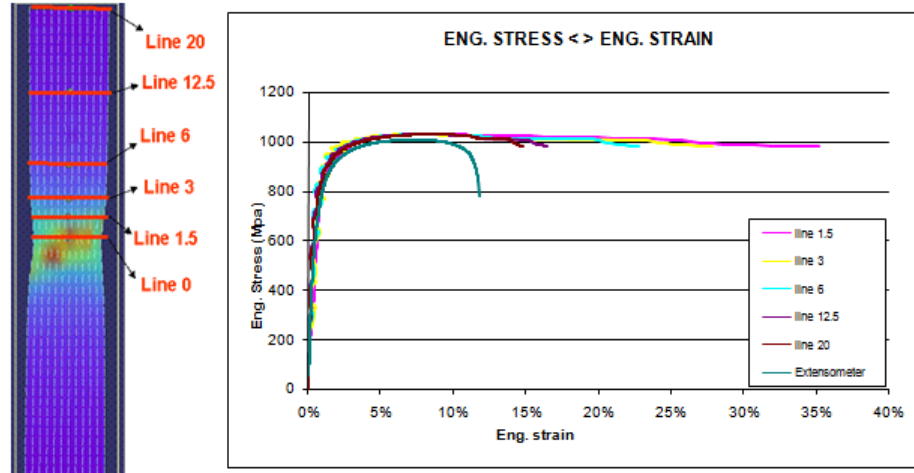

Fig. 12 Effect of gauge length on Eng. strain-stress curve

The n and r values are also measured in the fracture region, as shown in Figure 13 and Figure 14 respectively. As strain increases, the r value decrease, n value varies. N value is higher at the lower strain level, then decrease as strain increasing, rises in high strain.

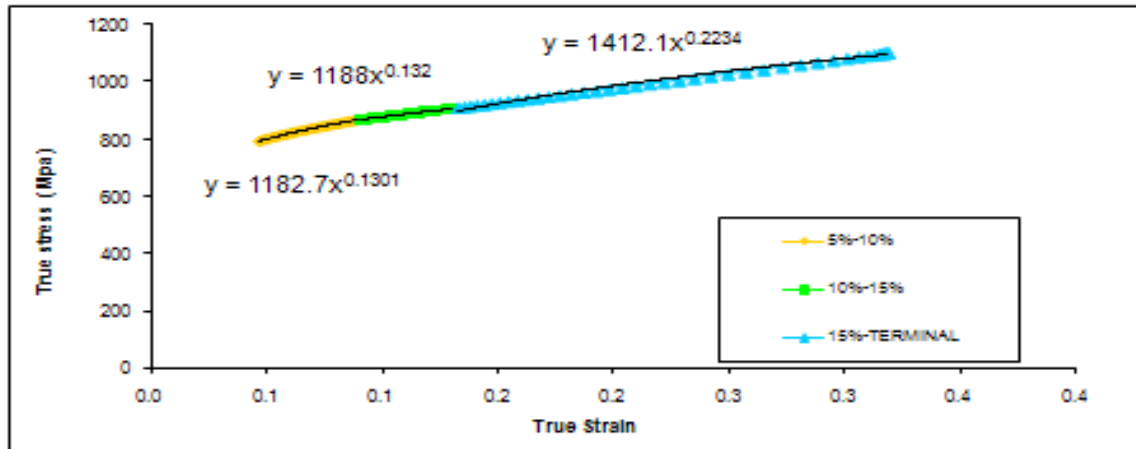

Fig. 13 Power law strain hardening and strength coefficients as a function of strain

n value for 5% to 10%= 0.1134	$\delta = 1182.7\epsilon^{0.1134}$
n value for 10%to 15%= 0.132	$\delta = 1188\epsilon^{0.132}$
n value for 15% to Terminal =0.2234	$\delta = 1412.1\epsilon^{0.2234}$

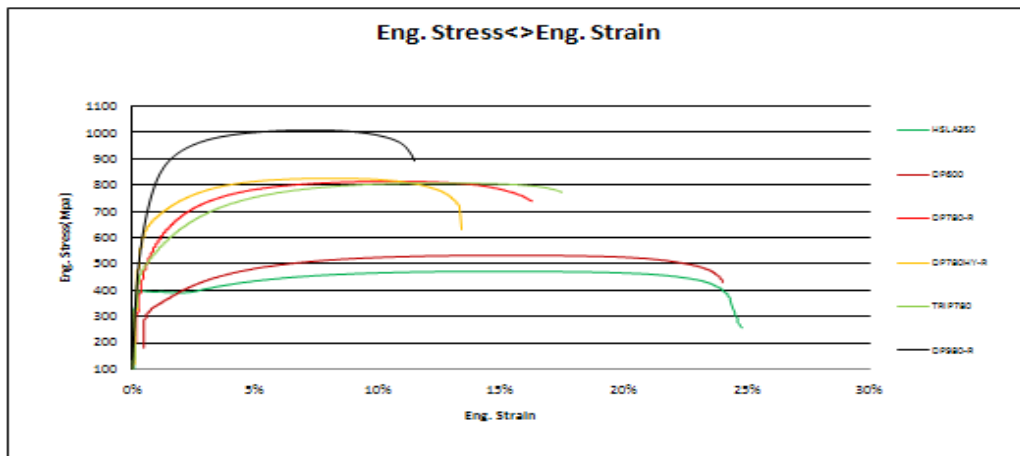

Fig. 14 Normal anisotropy coefficients as a function of strain

$$\begin{aligned}\epsilon_{major} + \epsilon_{minor} + \epsilon_t &= 0 \\ \epsilon_{minor} / \epsilon_t &= r\end{aligned}$$

8. Comparison of Different Materials

In this section, different material and test case are compared and they are described in the following figures.

9. Conclusions

DIC provides whole field true strain measurement well into the diffuse necking region.

DIC can measure true strain at any point in the specimen, while the average strain is obtained with the traditional method.

DIC can measure true strain at any point in the specimen, while the average strain is obtained with the traditional method.

DIC can be used to accurately analyze the necking process. The fracture strain is much higher than the total elongation measured with the traditional method.

The gage length effect analysis shows that the fracture strain increases significantly as the gage length changes from standard length (50mm) to 2mm.

As strain increases, the r value decreases, and the n value varies (high-low-high).

In higher strain rate measurement, the stress is slightly higher and the strain is much higher than quasi static results.

In comparison of maximum strain between HSLA350 and DP600, the results from extensometer are slightly different, while the DIC results show that HSLA350 strain is much higher than that of DP600.
